Abstract

In an attempt to characterize material intrinsic reactivity, iron dissolution from elemental iron materials (Fe⁰) was investigated under various experimental conditions in batch tests. Dissolution experiments were performed in a dilute solution of ethylenediaminetetraacetate (Na₂-EDTA - 2 mM). The dissolution kinetics of eighteen Fe⁰ materials were investigated. The effects of individual operational parameters were assessed using selected materials. The effects of available reactive sites [Fe⁰ particle size (≤2.0 mm) and metal loading (2-64 g L⁻¹)], mixing type (air bubbling, shaking), shaking intensity (0-250 min⁻¹), and Fe⁰ pre-treatment (ascorbate, HCl and EDTA washing) were investigated. The data were analysed using the initial dissolution rate (k₇EDTA). The results show increased iron dissolution with increasing reactive sites (decreasing particle size or increasing metal loading), and increasing mixing speed. Air bubbling and material pre-treatment also lead to increased iron dissolution. The main output of this work is that available results are hardly comparable as they were achieved under very different experimental conditions. A unified experimental procedure for the investigation of processes in Fe⁰/H₂O systems is suitable. Alternatively, a parameter (τ₇EDTA) is introduced which could routinely used to characterize Fe⁰ reactivity under given experimental conditions.

Key words: EDTA; Electrochemical reactivity; Operational parameters, Water Remediation; Zerovalent iron.
1. Introduction

Elemental iron ($\text{Fe}^0$) is a well known material for the abiotic removal of organic and inorganic contaminants from groundwater, soils, sediments, and waste streams [1-14]. $\text{Fe}^0$ is widely termed in the literature on permeable reactive barriers as zerovalent iron (ZVI) and is available as $\text{Fe}^0$-based alloys ($\text{Fe}^0$ materials), mostly cast iron and low alloy steel. Reduction through electron transfer from the body of the $\text{Fe}^0$ (direct reduction) is currently considered as the main removal mechanism for the majority of contaminants in $\text{Fe}^0$/H$_2$O systems [4, 9, 15].

However, for this thermodynamic founded assumption to be realized, the $\text{Fe}^0$ surface has to be accessible to the contaminant species. Alternatively, the surface must be covered by an electron conductive oxide-film (e.g. $\text{Fe}_3\text{O}_4$). In all cases, experiments are to be conducted under conditions which closely mimic those found in nature. In particular, mixing of the solution should neither delay nor prevent the formation of an oxide-film in the vicinity of the $\text{Fe}^0$ surface [16, 17]. This aspect of mixing has been mostly overseen since mixing is essentially used as a tool to accelerate contaminant transport to $\text{Fe}^0$ surface [18, 19]. This example illustrates the necessity of exploring and/or revisiting the influence of operational parameters on the processes of iron dissolution which is coupled to contaminant removal.

In the last fifteen years a huge number of studies have been conducted with the aim to understand the impact of operational conditions on the processes of contaminant removal in Fe$^0$/H$_2$O systems [2, 15, 18, 20-23]. The investigated experimental conditions included: Fe$^0$ characteristics, Fe$^0$ type, Fe$^0$ particle size, dissolved oxygen, contaminant concentration, solution chemistry (e.g. pH, dissolved ligands), chemical modification of the original material, mixing type, mixing intensity and material loading. In these studies, the influence of the operational conditions on the removal efficiency for the respective contaminants was reported to be theoretically expected and experimentally verified. For instance, while investigating the effects of mixing intensity (min$^{-1}$) on nitrate removal by nanoscale Fe$^0$, Choe et al. [20] found out that for mixing intensities <40 min$^{-1}$ NO$_3^-$ removal is largely a mass
transport-limited surface reaction, the reaction taking place at the Fe\(^0\)/H\(_2\)O interface. However, from open literature on corrosion it is known that under natural conditions (near-neutral pH, slowly flowing groundwater) such an interface does not exist due to the ubiquitous presence of iron oxide that coats the metal surface [24-27] and provides two interfaces; Fe\(^0\)/Fe-Oxide and Fe-Oxide/H\(_2\)O. The fact that at pH>4.5 an iron surface is always covered with an oxide-film has been recognized in the reactive wall literature [28-31]. For example Chen et al. [29] used a 50 mM ethylenediaminetetraacetate (EDTA) solution to avoid oxide-film formation in their investigations on trichloroethylene degradation by Fe\(^0\). Because the oxide-film is omnipresent at the Fe\(^0\) surface, the interactions of any contaminant in Fe\(^0\)/H\(_2\)O systems will depend on the nature (composition, conductivity, porosity, thickness) of the formed film and the affinity of the contaminant for the film material. Therefore, it is suitable to characterize Fe\(^0\) reactivity and the effects of operational conditions in systems exempt from in situ generated oxide-films [31]. As a strong iron complexing agent without redox properties EDTA has been used successfully for this purpose [32, 33]. In these previous works [32, 33], a positive correlation between the extend of uranium (VI) removal and the dissolution rates in 2 mM EDTA (k\(_{\text{EDTA}}\)) was demonstrated for thirteen Fe\(^0\) materials. Recent data on methylene blue discoloration by the same materials corroborated reported results [18]. The present study aims to assess the ability of various Fe\(^0\) materials to release Fe (Fe\(^{II}\), Fe\(^{III}\) species) into a 2 mM EDTA solution and to establish the response of selected Fe\(^0\) materials to a relative wide range of experimental conditions. The effects of Fe\(^0\) particle size (≤2.0 mm) and metal loading (2-64 g L\(^{-1}\)), mixing type (air bubbling, shaking), shaking intensity (0-250 min\(^{-1}\)), and Fe\(^0\) pre-treatment (ascorbate, HCl and EDTA washing) on Fe dissolution in batch operation mode were investigated and the degree of influence of each examined experimental parameter is discussed.

2. Some relevant aspects of the “Fe\(^0\)/EDTA/H\(_2\)O” system
Dissolution studies are commonly used as a tool to characterize the reactivity (or stability) of geological materials [34-38]. Using this tool the oxidative dissolution of Fe\(^0\) materials can be investigated at approximately neutral pH in order to simulate pH conditions characteristic of natural groundwaters [39]. Since the solubility of iron in this pH range is very low, EDTA can be used to sustain material dissolution [28, 29, 31]. Table 1 summarises some relevant reactions occurring in a “Fe\(^0\)/EDTA/H\(_2\)O” system. A very comprehensive review on the chemistry of the “Fe\(^0\)/EDTA/H\(_2\)O” system is given by Pierce et al. [31].

In this system, Fe\(^0\) dissolution is an oxidative process mediated by water (Eq. 1) or dissolved oxygen (Eq. 2). The resultant Fe\(^{2+}\) ions can be further oxidized to Fe\(^{3+}\) by dissolved O\(_2\) (Eq. 3) or complexed by EDTA, yielding [Fe\(^{II}\)(EDTA)] and [Fe\(^{III}\)(EDTA)] complexes (Eqs. 4, 5). [Fe\(^{II}\)(EDTA)] complexes are highly sensitive to dissolved oxygen, and oxidative transformation to more stable [Fe\(^{III}\)(EDTA)] complexes is completed in less than 1 minute [40, 41]. Equations 6 to 8 illustrate the formation of corrosion products and their complexive dissolution by EDTA. Corrosion products are usually mixture of iron oxides (FeOOH, Fe\(_2\)O\(_3\), Fe\(_3\)O\(_4\)); it is expected, that the kinetics of their EDTA dissolution will primarily depend on the crystalline structure of individual oxides [42].

The basic approach of this study is to exploit the differences in initial dissolution behaviour of Fe\(^0\) materials in a dilute EDTA solution (2 mM) in order to characterize their intrinsic reactivity [32, 33] and also to investigate the response of the system to changes in some relevant operational parameters. Using a metal loading of 10 g L\(^{-1}\) previous works have shown that the dependence of the iron concentration on the elapsed time for the material termed ZVI\(_0\) here was a linear function (Eq. 9) for the first 72 hours of the experiment [32, 33]. In Eq. 9 [Fe]\(_t\) is the total iron concentration at time \(t\) as defined by Eq. 10

\[
[Fe]_t = k_{EDTA}*t + b \quad (9)
\]

\[
[Fe]_t = [Fe^{II}]_t + [Fe^{III}]_t + [Fe^{II}\text{(EDTA)}]_t + [Fe^{III}\text{(EDTA)}]_t \quad (10)
\]
The current study was targeted at identifying the time frame for which the linearity of Eq. 9 is assured for the systems \( \text{Fe}^0 (2 \text{ g L}^{-1}) / \text{EDTA} (2 \text{ mM}) \). For each ZVI material the linear dissolution function obtained from experiment can be used to characterise the individual reactivity, with the linear gradient (‘\( k_{\text{EDTA}} \)’ in Eq. 9) representing the rate of iron dissolution (\( k_{\text{EDTA}} \)) and the intercept (‘\( b \)’ in Eq. 9) representing the iron concentration at \( t_0 \) (ideally zero; \( b = [\text{Fe}^0]_{t_0} \)), and providing an estimation of the amount of possibly readily soluble atmospheric corrosion products on the material. Ideally, under given experimental conditions, Fe concentration increases continuously with time from 0 mg L\(^{-1}\) at the start of the experiment (\( t_0 = 0 \)) to 112 mg L\(^{-1}\) (0.002 M) at saturation (\( t_{\text{sat}} = \tau_{\text{EDTA}} \)) when a 1:1 complexation of Fe and EDTA occurs. Thus, \( \tau_{\text{EDTA}} \) is an operative parameter which could allow the characterization of the reactivity of each Fe\(^0\) under any experimental conditions [43].

An independent process involving Fe\(^0\), EDTA and molecular O\(_2\) was developed by Noradoun and co-workers [44, 45] and is currently further developed [46-48]. This process uses the “zerovalent iron, EDTA and air” system (ZEA system) to generate HO\(^+\) radicals for contaminant oxidation. In this process, EDTA itself is degraded [46]. Moreover, Gyliene et al. [49] have recently used Fe\(^0\) for aqueous quantitative removal of up to 100 mM EDTA. The removal mechanism included degradation by HO\(^+\) radicals and co-precipitation with iron corrosion products. The results of Gyliene et al. [49] indicate that under the experimental conditions of this work, EDTA (2 mM) could be removed only by degradation since the Fe\(^0\) reactivity characterization is limited to the pre-saturation phase (no precipitation). In total, recent works on the Fe\(^0\)/EDTA/H\(_2\)O system, clearly demonstrated that EDTA is a concurrent contaminant for in situ generated oxidative species and should be regarded as instable.

The present study can be seen as an investigation of the short-term kinetics of iron dissolution in ZEA systems while characterizing the effects of operational parameters on this process. Clearly, a well documented methodology is used to characterize Fe\(^0\) reactivity as influenced by operational parameters. In this method dissolved oxygen is a reactant and not a disturbing
factor. Furthermore, since the investigations are limited to the initial phase of iron dissolution (forward dissolution), the possibility that EDTA alters the corrosion process is not likely to be determinant [31]. Theoretically, EDTA should not deplete during this initial reaction phase which is dominated by forward iron dissolution. The well-documented instability of Fe$^{III}$-EDTA complexes (photodegradation) is the sole concern here [50].

3. Material and methods

3.1 Solutions

Based on previous works [32, 33], a working EDTA solution of 0.002 M (or 2 mM) was used in this study (also see the discussion in the Supporting Information). The working-solution was obtained by one step dilution of a commercial 0.02 M standard from Baker JT® with Milli-Q purified water. A standard iron solution (1000 mg L$^{-1}$) from Baker JT® was used to calibrate the Spectrophotometer. All other chemicals used were of analytical grade. In preparation for spectrophotometric analysis ascorbic acid was used to reduce Fe$^{III}$-EDTA in solution to Fe$^{II}$-EDTA. 1,10 orthophenanthroline (ACROS Organics) was used as reagent for Fe$^{II}$ complexation prior to spectrophotometric determination. Other chemicals used in this study included Na$_2$-EDTA, NaHCO$_3$, L(+)-ascorbic acid, L-ascorbic acid sodium salt, and sodium citrate. The initial pH of the working EDTA solutions was 5.2 and increased to values above 8.0 as result of iron corrosion.

3.2 Fe$^0$ materials

A total of eighteen (18) ZVI materials (ZVI0 through ZVI17) were obtained from various sources, in different forms and grain sizes. The main characteristics of these materials including form, grain size and elemental composition are summarized in Tables SI1 and SI2 (Supporting Information). No information about manufacturing processes (e.g. raw material, heat treatment) was available to assist with subsequent data interpretation. It is well reported that the specific surface area (SSA) of iron materials is one of the predominant factors in controlling reactivity and is directly related to grain size [51-53]. The materials investigated in
this study have a variety of different grain sizes (<80 μm to 9000 μm) with resultant differences in specific surface area, although exact values were not available or determined. However, it was not the objective of this study to investigate the impact of the specific surface area on the reactivity of these different materials, but rather to compare the reactivity of the materials in their typical state (and form) in which they might be used for field applications. Apart from samples ZVI0, ZVI7 and ZVI11, all materials were used for experiment in an ‘as received’ state. Samples ZVI0, ZVI7 and ZVI11 were crushed and sieved, with the grain size fraction between 1 mm and 2 mm selected for reaction.

3.3 Iron dissolution experiments

Three different types of batch experiments were conducted at room temperature (~22 °C) for experimental durations varying from 0.5 to 120 hours. The types of experiment are described in more detail in the following section:

**Type 1 open systems:** Iron dissolution was initiated by the addition of 0.1 g of each material to 50 mL of a 2 mM EDTA solution (2 g L⁻¹ ZVI). Each reaction was run for ≤144 hours (6 days) in triplicate using narrow 70 mL glass beakers to hold the solutions. The reacting samples were left undisturbed on the laboratory bench for the duration of experimental period and were shielded from direct sunlight to minimize Fe³⁺-EDTA photodegradation [50]. These open systems (type 1) were used to characterize: (i) the reactivity of all used Fe⁰ (k_{EDTA}, b and τ_{EDTA} values), and (ii) the effects of particle size and mass loading.

**Type 2 open systems:** Dissolution was initiated by the addition of 0.2 g Fe⁰ material in a sealed vessel containing 100 mL of EDTA solution (2 g L⁻¹ ZVI). Experiments were conducted for ≤96 hours (4 days) in specially manufactured glass reaction vessels (~125 mL capacity) designed to allow continual mixing of the EDTA solution using a current of humid air supplied by a small aquaristic pump. The setup was designed to homogenize the experimental solutions at atmospheric pressure whilst keeping Fe⁰ materials immobile at the bottom of the vessels. Experiments in type 2 open systems were performed to investigate the
impact of mixing art on the process of Fe\textsuperscript{0} dissolution. Parallel experiments (non-shaken, ultrasound) were performed in the same vessels to account for possible influence of the reactor geometry.

**Closed systems:** For each dissolution reaction 0.2 g of the Fe\textsuperscript{0} material was added to 100 mL EDTA solution (2 g L\textsuperscript{–1} ZVI) in sealed polypropylene Erlenmeyer flasks (Nalgene\textsuperscript{®}). Each reaction was run for ≤96 hours (4 days) in triplicate. For each experiment the Erlenmeyers were placed on a rotary shaker or in an ultrasonic bath and allowed to react. The shaking intensities used for different samples were 0, 50, 150, 200 and 250 min\textsuperscript{–1}. Closed systems were performed to investigate the effects of mixing intensity.

At various time intervals, 0.100 to 1.000 mL (100 to 1000 μL) of the solution (non filtrated) were withdrawn from the Erlenmeyer flask with a precision micro-pipette and diluted with distilled water to 10 mL (test solution) in 20 mL glass essay tubes in preparation for analysis. After each sampling the equivalent amount of distilled water was added back into the Erlenmeyer in order to maintain a constant volume.

### 3.4 Analytical method

The aqueous iron concentration was determined with a Varian Cary 50 UV-VIS spectrophotometer, using a wavelength of 510 nm and following the 1,10 orthophenanthroline method [54, 55]. The instrument was calibrated for iron concentration ≤10 mg L\textsuperscript{–1}.

The pH value of each sample was measured by combination glass electrodes, that were pre-calibrated with five standards following a multi-point calibration protocol [56] and in accordance with the new IUPAC recommendation [57].

X-ray photoelectron spectroscopy (XPS) was used to identify the atmospheric corrosion products present at the surface of samples ZVI0 and ZVI8. Samples were mounted and analysed under high vacuum (≤5 10\textsuperscript{−8} mbar) in a Thermo VG Scientific X-ray photoelectron spectrometer (XPS) equipped with a dual anode X-ray source (Al K\textalpha\textsuperscript{1} 1486.6 eV and Mg K\textalpha\textsuperscript{1}...
1253 eV). Al Kα radiation was used at 400W (15 kV) and high resolution scans were acquired using a 30 eV pass energy, 0.1 eV step size and 200 ms dwell times.

4. Results and discussion

4.1 Expression of experimental results

Given that the initial rate of iron dissolution for each material was expected to follow a linear function \([\text{[Fe]}_t = k_{\text{EDTA}} \times t + b]\), regression of the experimental data (Fe concentration versus reaction time) allowed calculation of the linear dissolution function for each individual material. Direct comparison of the calculated rates of iron dissolution \(k_{\text{EDTA}}\) could be used to indicate the more reactive ZVI materials, whilst the calculated intercept ('b') values could be used to indicate the relative amount of pre-existing corrosion products present on the material surfaces. To further characterize \(\text{Fe}^0/\text{EDTA}\) systems, a new parameter is introduced \((\tau_{\text{EDTA}})\).

Per definition, \(\tau_{\text{EDTA}}\) for a given system is the time required for the iron concentration to reach 2 mM (112 mg L\(^{-1}\)); that is the time to achieve saturation assuming 1:1 complexation of \(\text{Fe}^{\text{II,III}}\) by EDTA. Thus, \(\tau_{\text{EDTA}}\) is the solution of the equation \(k_{\text{EDTA}} \times t + b = 112\). The regression parameters of the experimental data are summarised in two tables (Table 2 and Table 3).

4.2 Qualitative XPS analysis

XPS results from analysis of materials ZVI0 and ZVI8 before experimental reaction clearly indicated that the uppermost surfaces of the two materials were iron oxide. The binding energy of the recorded Fe 2p lines was typical of \(\text{Fe}^{\text{III}}\) in \(\text{Fe}_2\text{O}_3\) (hematite), although there was some evidence for a minor \(\text{Fe}^{\text{II}}\) oxide (magnetite/wüstite) component. No signal was recorded from the metal, indicating that the materials had a universal oxide coating of at least 10 nm equivalent to the maximum escape depth of photoelectrons from the sample. This result highlights, in agreement with the literature [58-60], the fact that most \(\text{Fe}^0\) materials will typical possess a surface oxide coating prior to their use in environmental applications. It has been shown that these coatings are rapidly removed from \(\text{Fe}^0\) surfaces upon immersion by an auto-reduction reaction [59, 60]. Removed oxide layers (mostly \(\text{Fe}_2\text{O}_3\)) are subsequently
transformed to magnetite and green rust, which will not inhibit the process of contaminant reduction [59]. However, because reduction is not the fundamental contaminant removal mechanism in Fe\textsuperscript{0}/H\textsubscript{2}O systems [16, 17], it is still interesting to quantify the amount of oxide coatings.

### 4.3 Effect of operational parameters

Among the tested materials ZVI4 (fillings) was one of the materials exhibiting the largest particle size distribution while exhibiting relative low proportion of fines. ZVI4 was resultantly used in investigations regarding the effects of particle size. Other parameter-testing experiments were conducted with ZVI8 or ZVI0. The preference for ZVI8 is justified by its spherical form, its minor dissolution reactivity (\(k_{\text{EDTA}}\) and \(\tau_{\text{EDTA}}\) in Table 2) and the fact that the material is rusted and could recover its metallic glaze only after HCl or ETDA washing. While using a less reactive material in experiments where reactivity enhancement is expected (e.g., metal loading, mixing intensity), a large window of opportunity is expected before solution saturation ([Fe] < 112 mg L\textsuperscript{-1}). The available surface area of ZVI8 was estimated using the relation \(S = 6/\rho d\) [61], where \(\rho\) is the density (7,800 kg m\textsuperscript{3}) of Fe\textsuperscript{0} and \(d\) the particle diameter (\(d = 1.2\) mm, Table SI 1).

### 4.3.1 Effect of Fe\textsuperscript{0} type

Eighteen types of Fe\textsuperscript{0} materials (Tables SI 1 and SI 2) were evaluated using the EDTA dissolution method described (Type 1 open system). The calculated dissolution rates (\(k_{\text{EDTA}}\)) are displayed in Table 2 and vary from 1.3 to 111 \(\mu\)g h\textsuperscript{-1}. The large range in reactivity rations recorded for the materials indicates variability in reactivity between the Fe\textsuperscript{0} materials. The most reactive material was ZVI 16 (\(\tau_{\text{EDTA}} = 2.1\) d) displaying a dissolution rate of 111 \(\mu\)g h\textsuperscript{-1}. Scrap iron sample ZVI 7 displayed the lowest dissolution rate (1.3 \(\mu\)g h\textsuperscript{-1}) indicating extremely limited reactivity. The intrinsic difference in the reactivity of various Fe\textsuperscript{0} materials may be considered as a significant source for controversial and variable results observed in the literature [18, 19].
The general reactivity trend based on the material form was: powder > fillings > granular. Table 2 shows that some powders (ZVI11, ZVI12, ZVI13) are less reactive than ZVI6 (fillings). This result is mostly justified by the agglomeration of powders under the experimental conditions (non-shaken). Therefore, the EDTA-test may not be appropriate for some powdered materials (d <0.1 mm). The results with ZVI15 (finer grade), ZVI16 (medium grade) and ZVI17 (coarser grade) from Connelly-GPM, Inc. demonstrated that large amounts of fines yield to increased but meaningless b values. Being from the same manufacturer, the three materials have the same chemical composition. Because these materials were used “as received” the observed high b values can be attributed to the proportion of fines.

### 4.3.2 Effect of metal loading

The effect of the amount of ZVI8 on iron dissolution in 2 mM EDTA was investigated. The material was pre-washed in 50 mL of a 0.25 M HCl for 14 hours to remove surface corrosion products and minimize their subsequent interference. It was found that the rate of iron dissolution increased as the amount of Fe\(^0\) was increased from 2 g to 64 g L\(^{-1}\) (or 12 to 410 cm\(^2\) L\(^{-1}\)) (Table 3). However, the increase in iron dissolution rates was not linearly proportional to the increase in the amount of Fe\(^0\) reacted (Figure 1). For amounts of material \(\leq 16\) g L\(^{-1}\) the observed dissolution rates increased at a linear rate with increasing metal loading (R = 0.943) and a normalised iron dissolution rate of 6.2 \(\mu\)g h\(^{-1}\) cm\(^{-2}\) was estimated. Dissolution rates recorded for metal loads >16 g L\(^{-1}\) did not increase at a linear rate. For a more reactive material (e.g. ZVI11) the linearity range would be expected to be lower than for ZVI8 i.e. <16 g L\(^{-1}\). In fact, the more reactive a material the more rapid the kinetics of iron dissolution and thus the shorter the time to solution saturation. 16 g L\(^{-1}\) metal load of ZVI8 corresponds to 102 cm\(^2\) L\(^{-1}\) available surface.

The surface normalized reaction constant (\(k_{SA}\)) is frequently used in evaluating kinetic data from elemental iron reactions and in comparing iron reactivity toward various classes of compounds [51]. The key relationship behind the normalization procedure is linear...
proportionality between the rate constants and metal loading. There has been controversy over
validity of $k_{SA}$ for normalizing the rate constants by metal loading ([21, 62, 63] and references
therein]. The results above show that for ZVI8 and under non-shaken conditions linearity is
observed only for $[ZVI] \leq 16$ g L$^{-1}$ (102 cm$^2$ L$^{-1}$). It should be emphasized that mixing will
lower this critical mass loading for ZVI8 because of accelerated transport of molecular O$_2$ to
the Fe$^0$ surface. The large majority of experiments are conducted under mixing conditions and
with larger metal loadings. Therefore, the reported significant variations among $k_{SA}$ data (even
for a given compound) are difficult to interpret. In the future this comparison should be eased
by routinely given $\tau_{EDTA}$ for each experimental condition.

It is interesting to note that a certain linearity trend of b value as function of mass loading was
observed ($R = 0.854$). This linear dependence of b values from the metal loading validates the
enounced signification of that parameter. In this experiment corrosion products resulted from
the air oxidation of Fe$^0$ during the time elapsed between stopping HCl washing and initiating
EDTA dissolution. Therefore, the corrosion products didn’t have time to precipitate and/or
crystallize. As shown above (XPS results), Fe$^0$ materials are covered with amorphous and
crystalline iron oxides with differential dissolution behaviour. For granular materials as ZVI8,
it is assumed that the dissolution of iron oxide in EDTA is more favourable than the oxidative
dissolution of Fe$^0$ from the material. This assumption is the support of the significance of b
values and could be verified for ZVI0 and ZVI8 used in parallel “as received”, 2 mM EDTA-
 washed, and 250 mM HCl-washed experiments [32]. For materials with large amounts of
fines (e.g. powdered materials and ZVI16/ZVI17), however, b values were proven
meaningless. Because $k_{EDTA}$ and b values are not independent parameters, erroneous b values
have an incidence on the validity of $k_{EDTA}$. Therefore, the EDTA-test should be limited to
coarser material (d > 150 μm). Alternatively, Fe$^0$ materials can be compared on the basis of
extent of leached Fe in column studies (e.g. starting from 1 g of each material). In column

12
studies saturation is not expected and the differential dissolution of Fe\(^0\) and Fe oxide can be better characterized.

The comparison of \(a\) and \(\tau_{\text{EDTA}}\) values (Table 3) for the individual metal loadings shows that reactivity increased 6 fold as the metal loading varies from 2 to 64 g L\(^{-1}\). Considering that essentially higher metal loadings (up to 200 g L\(^{-1}\) and more) are used by several researchers another discrepancy source is identified. As discussed above higher metal loadings are directly related to more iron oxides generation, that are more adsorption sites for all contaminants, including metals and radionuclides. Therefore, in investigating the process of contaminant removal by Fe\(^0\) materials, the less possible metal loading should be used [63]. Considering that ZVI8 contains 92 % Fe, the molar ratio Fe:EDTA varies from 1 to 26 as the mass loading varies from 2 to 64 g L\(^{-1}\). This result shows that, apart from the experiment with 2 g L\(^{-1}\), Fe\(^0\) was available in excess. Characterizing the availability of Fe from the metal structure is a part of this study (see “Effect of Fe\(^0\) type”) but using over proportional material excess complicates mechanistic investigations for example. For instance, a lag time (induction time) was reported in the process of contaminant removal by Fe\(^0\) materials [3]. This study shows that the initial iron dissolution is always fast. Therefore, the reported lag time is possibly the time necessary for enough iron oxides to precipitate and adsorb contaminants. Adsorbed contaminants can be further transformed, e.g., reduced by: (i) dissolved Fe\(^{II}\), (ii) oxide-bounded Fe\(^{II}\), (iii) atomic (H) or molecular (H\(_2\)) hydrogen.

### 4.3.3 Effect of Fe\(^0\) particle size

The effect of Fe\(^0\) particle size on the iron dissolution in 2 mM EDTA was investigated using ZVI4. The material was sieved into six particle fractions (Table 3) and an equal mass of each was reacted. The results show increased rates of iron dissolution (increasing \(k_{\text{EDTA}}\) or decreasing \(\tau_{\text{EDTA}}\)) with decreasing particle size. The evolution of the curve \(\tau_{\text{EDTA}} = f(d)\) (not shown) suggests that according to particle size, three ranges of reactivity can be distinguished:
(i) very reactive \((d \leq 0.2 \text{ mm}, \tau_{\text{EDTA}} < 3 \text{ d})\) corresponding to linear increasing of \(\tau_{\text{EDTA}}\) with increasing \(d\); (ii) fairly reactive \((0.2 \leq d(\text{mm}) \leq 0.8, 3 < \tau_{\text{EDTA}} (d) < 5)\), corresponding to a plateau in the variation \(\tau_{\text{EDTA}}\) with \(d\); and (iii) less reactive \((0.8 \leq d(\text{mm}) \leq 2.0, \tau_{\text{EDTA}} > 5 \text{ d})\).

This classification suggests that only materials of similar particle sizes should be used in comparative investigations. Based on experimental results it is recommended that for testing micro-scale Fe\(^0\) materials with the EDTA method only particle diameters between 0.1–1.0 mm should be tested, ensuring that fines \((d \leq 0.1 \text{ mm})\) are separated by sieving (or washing).

The comparison of \(k_{\text{EDTA}}\) and \(\tau_{\text{EDTA}}\) values for the individual particle sizes shows that dissolution rate significantly decreases as the particle size was varied from \(\leq 0.125\) to 2.0 mm. This increase of reactivity with decreasing particle size is the rational of using nanoscale Fe\(^0\) for environmental remediation [61].

### 4.3.4 Effect of material pre-treatment

The effect of material pre-treatment was investigated in open systems with a metal loading of 5 g L\(^{-1}\). Four different pre-treatment procedures were tested. Pre-treatment consisted of washing 0.5 g of ZVI in 50 mL treatment solution for 14 hours. The treatment solutions included: (i) deionised water (as a reference system), (ii) 0.115 M ascorbate buffer, (iii) 0.02 M EDTA, and (iv) 0.25 M HCl. The Fe\(^0\) samples were then rinsed three times with 50 mL deionised water before dissolution testing. The results presented in Table 3 showed that all pre-treatment procedures enhanced the reactivity of ZVI8. The observed iron dissolution rate varied from 560 \(\mu\text{g h}^{-1}\) for the reference system to 860 \(\mu\text{g h}^{-1}\) for the Fe\(^0\) system washed in 0.115 M ascorbate buffer. Calculated \(\tau_{\text{EDTA}}\) values confirmed that the greatest dissolution rate occurred in the ascorbate-treated system. It should be noted that the amount of solid material lost to dissolution during the pre-treatment procedure was not measured in this work.

Previously, Matheson and Tratnyek [2] reported a 15 % loss of iron mass during acid pre-treatment (3 hours in 3 % HCl), while Fe\(^0\) washing at neutral pH with ascorbate buffer was
found exclusively to dissolve surface corrosion products, leaving a fresh residual Fe$^0$ surface. Based on the current results it is suggested that ascorbate pre-treatment is a preferable procedure for removing surface corrosion from Fe$^0$ materials than HCl-washing which has previously been more commonplace.

While the effects of pre-treatment generally followed expectation (reactivity enhancement) the relevance of these procedures should be brought into question because Fe$^0$ materials used in reactive barriers are not commonly pre-treated prior to emplacement [64]. Even if materials were pre-treated before emplacement surface oxides would rapidly form, long before any significant quantity of contaminant inflow [20, 65].

4.3.5 Effect of mixing

In investigating contaminant removal by Fe$^0$ materials, sample mixing (mostly stirring or shaking) is commonly used as a tool for increasing the rate of reaction. For an inert material as activated carbon, mixing may have little or no effect on material reactivity. However, the thermodynamic instability of metallic iron (Fe$^0$) in aqueous solution [2, 66] is the primary reason for using elemental iron materials for groundwater remediation.

In undisturbed systems in the absence of EDTA, it is generally accepted that decreased Fe$^0$ reactivity observed at pH > 5 is coupled to increased iron precipitation. However, a system which is physically disturbed by mixing will exhibit even greater Fe$^0$ reactivity because the vigorous hydrodynamic conditions (turbulent flow) increase the rate and amount of iron dissolution/oxidation by: (i) breaking apart and subsequently preventing the aggregation of colloidal iron oxide and oxyhydroxide particles; (ii) continually exposing fresh Fe$^0$ material through fragment collisions that dislodge and/or remove corrosion products from the material surface, and (iii) causing enhanced oxygen entrainment (diffusion) from the laboratory atmosphere into solution, thereby increasing rates of oxidation. Mixing will also facilitate transport of contaminants and reactive species to the Fe$^0$ surface although in some cases contaminant desorption may be promoted [67].
In this section the effect of mixing on Fe$^0$ dissolution is presented. Experiments were performed with two materials (ZVI0 and ZVI8) and three mixing types (bubbling, sonification and shaking).

**4.3.5.1 Effect of mixing type**

Figure 2 summarises the effect of mixing type on the reactivity of ZVI0, the regression parameters and $\tau_{\text{EDTA}}$ are given in Table 3. The results clearly indicate that all types of sample mixing enhance Fe$^0$ reactivity. The dissolution rate varied from 33 $\mu$g h$^{-1}$ for the non-mixed system to 6154 $\mu$g h$^{-1}$ for the ultrasonically mixed system, which displayed the most rapid rate of iron dissolution. This result clearly show that while using different mixing devices and performing the experiments for the same duration (e.g. 4 h) various extents of Fe$^0$ dissolution was achieved yielding to various amounts of contaminant removal agents (Fe$^{II}$, H$_2$, Fe oxides). Characterizing each experimental procedure with $\tau_{\text{EDTA}}$ will certainly facilitate the discussion of achieved results.

**4.3.5.2 Effect of shaking intensity**

The effect of shaking intensity was investigated with ZVI8 for four different shaking rates: 50, 150, 200 and 250 min$^{-1}$. The results are summarized in Table 3 and follow theoretical predictions of enhanced dissolution behaviour with increasing mixing intensity. $\tau_{\text{EDTA}}$ varied from 3.7 days for a mixing intensity of 50 min$^{-1}$ to 0.4 days for 250 min$^{-1}$. The effect of shaking intensity is presented in more details elsewhere [43]. The results disprove the popular assumption that mixing batch experiments is a tool to limit or eliminate diffusion as dominant transport process of contaminant to the Fe$^0$ surface.

**4.3.5.3 Discussion**

Ultrasonic vibration and solution shaking involved the physical movement of both solution and Fe$^0$ materials. By comparison, solutions mixed by air-bubbling left the Fe$^0$ material immobile whilst homogenising the overlying solution.
The ‘bubbled’ metal-solution system recorded a 40 fold enhancement in reactivity compared to the non-disturbed system. The bubbling maintained a continuously replenished supply of dissolved oxygen to the solution, promoting Fe\(^0\) oxidation and yielding dissolved Fe\(^{II}\) and Fe\(^{III}\) which then complexed with EDTA. Results indicated a rapid initial dissolution rate for the first 10-15 hours (figure 2) which subsequently tailed off by 80 hours, showing a slight increase again to 120 hours. The observed tail-off in dissolution rate occurred after iron saturation ([Fe] > 112 mg L\(^{-1}\)) had been reached and can be attributed to iron oxide nucleation and precipitation. Bubbling supplied the system with unrealistic amounts of dissolved O\(_2\) which was unrealistic with regard to subsurface reactive walls. These conditions are encountered in above ground plant for wastewater treatment for which the Fe\(^0\)/H\(_2\)O system are also used [14].

Previous studies have found that sample agitation can disturb, delay or even prevent iron oxide precipitation at the Fe\(^0\) surface [15, 16, 67]. Such mixing may allow contaminant transport to the Fe\(^0\)/H\(_2\)O interface, an interface which can not exist in nature [24, 63, 65]. On this basis it can be argued that sample mixing and agitation may yield unrealistic results and should therefore be avoided when testing the reactivity of Fe\(^0\) materials for commercial use in reactive barriers [18, 19]. Note that all types of mixing devices can be used for above ground water treatment systems using Fe\(^0\). However, for subsurface applications, mixing should not significantly disturbed the dynamic process of oxide-film formation and transformation.

Although the results have shown that Fe\(^0\) reactivity and dissolution may be enhanced by elevated mixing intensities, the mixing process is also known to have an effect on iron oxide precipitation. It is well accepted that contaminants (including EDTA, see ref. [49]) can be entrapped in the matrix of precipitating iron oxides (co-precipitation). Typically, contaminant removal enhanced by mixing is considered to operate on the basis of maintaining a continual supply of freshly exposed Fe\(^0\) surfaces for contaminant uptake. However, it is entirely possible that their co-precipitation with iron oxide may provide a competing removal
mechanism. Even though co-precipitated contaminants can be further reduced by structural
Fe\textsuperscript{II} or atomic and molecular hydrogen (H, H\textsubscript{2}), the reaction can not quantitatively occur at the
Fe\textsuperscript{0} surface as commonly reported.

The effect of the mixing intensity on Fe\textsuperscript{0} reactivity confirms theoretical predictions but the
discussion above questioned the validity of mixing to accelerate contaminant transfer to the
Fe\textsuperscript{0} surface. It is possible that a critical value exists below which mixing may have limited
effect on oxide-film formation (e.g. 40 min\textsuperscript{-1} in [20] or 50 min\textsuperscript{-1} in [43]). However, mixing
always increases iron dissolution and the Fe\textsuperscript{0} surface is permanently covered with corrosion
products. Therefore, it may be advantageous to conduct initial work under stagnant conditions
and progressively increase the mixing intensity to discover which mixing speeds can be used
without major iron precipitation interference [19]. Clearly, works investigating the same
process can only be comparable if conducted under similar $\tau_{\text{EDTA}}$ conditions.

5. Concluding remarks

The current study aimed at developing a reliable method for comparing and characterising
different Fe\textsuperscript{0} materials under various experimental conditions. For this purpose an aqueous
dissolution method utilizing a dilute 0.002 M EDTA solution was adopted for the
experimental work. Results showed that: (i) iron dissolution in non disturbed experiments is a
powerful tool for material screening; (ii) mixing type, mixing intensity, particle size and Fe\textsuperscript{0}
loading enhance the material reactivity to various extents. In particular, material pre-
treatment, too rapid mixing speeds or too high Fe\textsuperscript{0} dosages may yield reproducible but non
realistic results. Since the investigated parameters are not independent from each other it was
necessary to introduce a parameter ($\tau_{\text{EDTA}}$) which allows a reliable characterization of Fe\textsuperscript{0}
reactivity under each experimental condition. Therefore, similar to iodine number for
activated carbon, $\tau_{\text{EDTA}}$ is introduced to characterise material reactivity. Ideally, any work
with Fe\textsuperscript{0} should specify $\tau_{\text{EDTA}}$ under the experimental conditions. However, despite its
practical simplicity, $\tau_{\text{EDTA}}$ is an extrapolation which accuracy depends on the amount of
corrosion products on original materials (b values). Therefore, \( k_{EDTA} \) is a better parameter to characterize the reactivity of each Fe\(^0\).

Whilst literature on Fe\(^0\) remediation predominantly assumes that contaminant removal mostly occurs through electrochemical reduction at the surface of Fe\(^0\) materials, the results of this study and related works [18, 19, 43, 63] indicated that under environmental conditions contaminant removal may primarily occur in conjunction with the dynamic process of precipitation of corrosion products (non selective process). The first proof for this statement is that Fe\(^0\)/H\(_2\)O systems have efficiently reduced some contaminants, oxidized some others, and even removed some redox-insensitive contaminants [9, 10, 46]. Therefore, oxidation and reduction should be regarded as subsequent processes in the presence of immersed corroding Fe\(^0\) (statement 1). The concept regarding adsorption and co-precipitation as fundamental contaminant removal mechanisms in Fe\(^0\)/H\(_2\)O system is based on statement 1. This concept has partly faced with very sceptic views [68, 69]. For example, The authors of [69] complained that this concept “is hardly acceptable since the role of the direct electron transfer in ZVI-mediated reactions is well established and generally accepted among the research community.” However, the well-accepted “role of direct electron transfer in ZVI-mediated reactions” was demonstrably a “broad consensus” as recognized by O’Hannesin and Gillham [4]. On the other hand, the authors of [68] were “mystified” by any possible convergence between the mechanism of uranium (U) and an organohalide in Fe\(^0\)/H\(_2\)O systems because “the topic of U(VI) reduction is clearly remote from that of organohalide reduction”. These two examples illustrate the difficulty in revising a well-established but inconsistent concept.

Fortunately, electrocoagulation (EC) using iron electrodes (Fe\(^0\) EC) is rigorously an electrochemically accelerated iron corrosion and has proven similar efficiency as passive Fe\(^0\)/H\(_2\)O systems for the removal of various chemical contaminants and pathogens [70-72]. For Fe\(^0\) EC no one has suggested Fe\(^0\) electrodes as reducing agents, because Fe\(^0\) is intentionally corroded to produce “flocs” for contaminant co-precipitation. The similarity
between passive Fe⁰/H₂O systems and Fe⁰ EC should convince the last sceptics. The scientific community will then concentrate on the further development of the technology.

Interestingly, the scientific community is on schedule to identify the "common underlying mechanisms for reactions" in iron walls that provide a confidence for non-site-specific design. Is this the case, then "site-specific treatability studies may only be required to fine-tune design criteria for the optimal performance of PRBs" [73]. The concept of contaminant adsorption/co-precipitation can be regarded as the first step to this goal. The scientific community should abandon the current approach which merit was to demonstrate the efficiency of Fe⁰ for several contaminants (and groups of contaminants). The challenge now is to incorporate future studies within a broad-based understanding of Fe⁰ remediation technology. In particular, the removal mechanism of individual contaminants by Fe⁰ materials has to be investigated under non disturbed conditions and with realistic metal loadings. The proper use of τ_{EDTA} and k_{EDTA} is a precious guide on this highway.

Acknowledgments

For providing the materials investigated in this study the authors would like to express their gratitude to the branch of the MAZ (Metallaufbereitung Zwickau, Co) in Freiberg (Germany), Gotthart Maier Metallpulver GmbH (Rheinfelden, Germany), Connelly GPM Inc. (USA), Dr. Ralf. Köber from the Institute Earth Science of the University of Kiel and Dr. Vera Biermann from the Federal Institute for Materials Research and Testing (Berlin, Germany). Mechthild Rittmeier and Rüdiger Pfaar are acknowledged for technical support. The manuscript was improved by the insightful comments of anonymous reviewers from Journal of Hazardous Materials. The work was granted by the Deutsche Forschungsgemeinschaft (DFG-No 626/2-1).
